

Solution of assignment 4, ST2304

August 1, 2016

Problem 1

Reload the data from assignment 3.

```
> heli <- read.csv("z:/folder/helicopterdata.csv")
> attach(heli)
```

1. We first log-transform the response variable, and then reanalyse the data using a three-way analysis of variance (ANOVA).

```
> logflighttime <- log(flighttime)
> loghelimod <- lm(logflighttime ~ size + wing + clip)
> anova(loghelimod)
Analysis of Variance Table
```

Response: logflighttime

	Df	Sum Sq	Mean Sq	F value	Pr(>F)
size	1	0.0783	0.0783	1.8078	0.1814
wing	2	8.1317	4.0659	93.8251	< 2.2e-16 ***
clip	1	2.0896	2.0896	48.2198	2.414e-10 ***
Residuals	115	4.9835	0.0433		

Signif. codes: 0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1

Just like in assignment 3, *size* is non-significant. Thus, we remove this variable and reanalyse the data.

```
> loghelimod2 <- lm(logflighttime ~ wing + clip)
> anova(loghelimod2)
Analysis of Variance Table
```

Response: logflighttime

	Df	Sum Sq	Mean Sq	F value	Pr(>F)
wing	2	8.1317	4.0659	93.176	< 2.2e-16 ***
clip	1	2.0896	2.0896	47.886	2.646e-10 ***
Residuals	116	5.0618	0.0436		

Signif. codes: 0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1

Then we compare the adjusted R^2 of the logtransformed and original model (*helimod* from assignment 3). We compare the complete models.

```

> summary(loghelimod)$adj.r.squared
[1] 0.6625815
> helimod <- lm(flighttime ~ size + wing + clip)
> summary(helimod)$adj.r.squared
[1] 0.7028989

```

The adjusted R^2 of this model is 0.663, while the complete model without the log transformation had an adjusted R^2 of 0.703. The alternative model does thus have a worse fit.

A short reminder (from Wikipedia): R^2 is the proportion of variability in a data set that is accounted for by the statistical model, and it provides a measure of how well future outcomes are likely to be predicted by the model. $R^2 = 1 - SS_{err}/SS_{tot}$, where SS_{tot} and SS_{err} = the total and residual sums of squares. Adjusted R^2 is a modification of R^2 that adjusts for the number of explanatory terms in a model: $R^2_{adj} = 1 - SS_{err}/SS_{tot} * df_t/df_e$, where df_t and df_e = the total and residual degrees of freedom.

2. The regression can again be written in the form of a multiple regression model

$$\begin{aligned}
\log(\text{flighttime}) = & \mu + \alpha_{small}x_{small} \\
& + \beta_{up}x_{up} + \beta_{down}x_{down} \\
& + \gamma_{yes}x_{yes} \\
& + \epsilon
\end{aligned}$$

We can look at the untransformed response by taking the exponential of both sides:

$$\begin{aligned}
\text{flighttime} = & e^{\mu + \alpha_{small}x_{small} + \beta_{up}x_{up} + \beta_{down}x_{down} + \gamma_{yes}x_{yes}} \\
= & e^{\mu + \alpha_{small}x_{small}} e^{\beta_{up}x_{up}} e^{\beta_{down}x_{down}} e^{\gamma_{yes}x_{yes}}
\end{aligned}$$

Because each x is either 0 or 1, each component of the formula will multiply the flighttime by for example either $e^{\alpha*1} = e^\alpha$ or $e^{\alpha*0} = 1$.

The summary table provides all estimates.

```

> summary(loghelimod)

```

Call:

```

lm(formula = logflighttime ~ size + wing + clip)

```

Residuals:

Min	1Q	Median	3Q	Max
-0.47272	-0.14327	0.03741	0.12800	0.56625

Coefficients:

Estimate	Std. Error	t value	Pr(> t)
----------	------------	---------	----------

```

(Intercept)  2.35093    0.04249  55.326 < 2e-16 ***
sizesmall   -0.05110    0.03801  -1.345  0.181
wingdown    -0.52747    0.04655 -11.332 < 2e-16 ***
wingup      -0.57401    0.04655 -12.332 < 2e-16 ***
clipyes     -0.26392    0.03801  -6.944  2.41e-10 ***

```

Signif. codes: 0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1

Residual standard error: 0.2082 on 115 degrees of freedom

Multiple R-squared: 0.6739, Adjusted R-squared: 0.6626

F-statistic: 59.42 on 4 and 115 DF, p-value: < 2.2e-16

We see that the estimated effect of attaching a clip is $e^{-0.264} = 0.768$, or 76.8% of the flighttime without a clip.

The estimated effect of a small helicopter is $e^{-0.051} = 0.95$, thus a small helicopter falls to the ground 5% faster relative to a large helicopter.

3. Confidence intervals are computed using `confint()`. The optional argument (`level`) allows one to specify the confidence interval required, but we will accept the default which give us 95% confidence intervals.

```

> confint(loghelimod)
              2.5 %      97.5 %
(Intercept)  2.2667584  2.43509676
sizesmall   -0.1263839  0.02418249
wingdown    -0.6196716 -0.43526624
wingup      -0.6662135 -0.48180810
clipyes     -0.3392007 -0.18863437

```

To transform these to confidence intervals in percent, we take the exponential and multiply by 100.

```

> exp(confint(loghelimod))*100
              2.5 %      97.5 %
(Intercept)  964.80753 1141.69233
sizesmall    88.12765  102.44773
wingdown     53.81211  64.70924
wingup       51.36498  61.76656
clipyes      71.23394  82.80892

```

Note that this does not make any sense for the intercept.

Problem 2

We download the data set and split it into two parts. `skip = 1` allows us to skip one row (the one with variable explanations) in the data set before we start reading data into R.

```
> grades <- read.csv("Z:/folder/Grade_prediction_data_2015.csv", skip = 1)
> trainingset <- grades[complete.cases(grades),]
> validationset <- grades[complete.cases(grades[, -2]) & is.na(grades$grade),]
> attach(trainingset)
```

1. We first make a scatterplot of all variables.

```
> pairs(grades[, -1])
```

Then we estimate all pairwise correlations.

```
> round(cor(grades[,sapply(grades,is.numeric)],use="complete.obs"), 2)
      grade lectures assignments nassign reading training alcohol

```

In multiple regression we assume no or little multicollinearity (correlation among explanatory variables). The variables *motivation* and *nassign*, *motivation* and *reading*, and *assignments* and *reading* seem to be somewhat positively correlated. All other correlations are lower and should not cause any problems in our multiple regression. However, even correlations as low as 0.28 has been found to bias analyses (Graham 2003 Ecology). Collinearity may cause (1) inaccurate model parameterization, (2) decreased statistical power, and (3) exclusion of significant predictor variables during model selection. With highly correlated explanatory variables care should be taken when constructing models. Here we will just keep all variables in the analyses. However, with very highly correlated variables (e.g. ≥ 0.7) one should use biological knowledge to construct the model that makes best sense while avoiding highly correlated variables in the same model.

2. We start by fitting the full model with all relevant additive terms. Then we examine

the parameter estimates (using `summary()`) and the significance of each term using F-tests (`drop1()` command). *A priori* we exclude the variables *facebook*, *fbfriends* and *work* as we do not see how these variables may affect the grade of students when we have direct measures of time spent studying for the course. *Partner* was considered irrelevant for the grades of student.

```
> # Fit
> mod0 <- lm(grade ~ sex + course + lectures + assignments +
+           nassign + reading + training + alcohol +
+           gaming + age + sleep + motivation)
> # Parameter estimates
> summary(mod0)
```

The F-values tests if the fit of your model changes if you would remove that explanatory variable, and the sums of squares tells us how much the sum of squares would change; the smaller the change in sum in squares, the smaller the F-value.

We decided to use a step-wise approach where we remove all non-significant terms in one go, then try to add each of the removed variables to the new model using `add1()`.

Another popular approach is to remove the explanatory variable with the lowest F-value in the `drop1()`-table in each step (e.g. using `mod1 <- update(mod0, .~.-sleep)`) until all variables are significant. Stepwise approaches are generally problematic due to the problem of multiple testing (i.e. 1 out of 20 tests will be significant by chance).

```

> mod1 <- lm(grade ~ lectures + assignments +
+           nassign + motivation)
> add1(mod1, .~. + sex + course + reading + training + alcohol +
+       gaming + age + sleep, test="F")

```

Residual standard error: 1.123 on 72 degrees of freedom

Multiple R-squared: 0.4289, Adjusted R-squared: 0.4051
F-statistic: 18.03 on 3 and 72 DF, p-value: 7.937e-09

We see that highly motivated students which complete many assignments perform better on the exam. On the other hand, students which spend a lot of time with assignments each week perform less well on the exam. This effect might at first glance seem surprising. However, it is likely that the students which spend a lot of time to complete assignments are those that struggle a lot with the course. These students most likely perform much better on the exam than if they had not spent a lot of time with assignments. Still, on average they perform less well than students which conquer the course straight away.

3. Finally we predict the grades of students with missing values in the data set.

```
> round(predict(mod2, validationset))  
3 5 6 10 15 16 17 18 19 21 23 24 25 27 29 31 33 40 42 43  
2 4 4 3 2 3 2 2 3 3 3 2 3 3 4 4 4 5 4 4
```

The predictions are all between 1 and 6 and seems to make sense. However, generally this model could predict grades above 6. The adjusted R^2 of the final model is 0.405, not much worse than the full model in task 1 (0.438). With only 40.5% of the variation in student grades explained by our model we should not expect the predictions to be to accurate.
